16. ABSTRACT <p>Tensile properties in defect-free weldments of aluminum alloys 2014-T6 and 2219-T87 (sheet and plate) are shown to be related to the level or concentration of induced simulated porosity. The scatter diagram shows that the ultimate tensile strength of the weldments displays the most pronounced linear relationship with the level of porosity. The relationships between yield strength or elongation and porosity are either trivial or inconsequential in the lower and intermediate levels of porosity content. In highly concentrated levels of porosity, both yield strength and elongation values decrease markedly.</p> <p>Correlation coefficients were obtained by simple straight line regression analysis between the variables of ultimate tensile strength and pore level. The coefficients were greater, indicating a better correlation, using a pore area accumulation concept or pore volume accumulation than the accumulation of the pore diameters. These relationships provide a useful tool for assessing the existing aerospace radiographic acceptance standards with respect to permissible porosity. In addition, these relationships, in combination with known design load requirements, will serve as an engineering guideline in determining when a weld repair is necessary based on accumulative pore level as detected by radiographic techniques.</p>

ACKNOWLEDGEMENTS

I would like to thank Mr. S. Hunter for his effort in mechanical property determinations, as well as the photographic work of Mr. B. Sandlin. In addition, I would like to acknowledge the support of Mr. P. Duren for his radiographic inspection of the welds. Gratification is also extended to Mr. B. Vardaman for his endless effort as technical editor of this report. These people are all members of the Materials and Processes Laboratory, MSFC.

TECHNICAL MEMORANDUM X-64933

EFFECTS OF POROSITY ON WELD-JOINT TENSILE
STRENGTH OF ALUMINUM ALLOYS

SUMMARY

Simulated porosity was introduced in weldments of aluminum alloys 2014-T6 and 2219-T87 (sheet and plate) by precision drilling. The simulated porosity was examined in terms of accumulative linear inch (cm) of pore diameters, accumulative volume, and accumulative area per unit length of weld, respectively. In addition, the summation of porosity area was expressed as percent pore area in a cross-sectional plane (cross-sectional area of tensile specimen). Each pore quantity was plotted against the corresponding ultimate tensile strength, yield strength, and elongation. The ultimate tensile strength of the weldments displayed the most significant correlation with the porosity concentration. The relationships between yield strength or elongation and porosity were either trivial or inconsequential in the lower and intermediate levels of porosity content. In highly concentrated levels of porosity, both yield strength and elongation values decreased markedly. Accumulative pore area and percent pore area in weldments of each base metal thickness displayed a very strong linear relationship with ultimate tensile strength. Simple straight line regression analysis showed correlation coefficients (r) which exceeded 0.900, and the square of the coefficients (r^2) were in excess of the numerical value 0.810. In essence, this means that more than 81 percent of the total ultimate tensile strength variation can be explained by the associated accumulative pore area. In some cases, the correlation coefficient actually surpassed the value of 0.980.

The ultimate tensile strength of each individual value (all thicknesses) was plotted as a function of corresponding percent pore area for weldments of each alloy. These combined data exhibited a correlation coefficient of 0.882 for weldments of aluminum alloy 2014-T6, and a correlation coefficient of 0.913 for weldments of alloy 2219-T87.

Tensile tests conducted at -320°F (-196°C) with 1/4-in. (0.635-cm) thick plate weldments also showed strong linear relationships between simulated porosity level and ultimate tensile strength. The order of decreasing correlation coefficients was (1) area, (2) volume, and (3) linear concepts. Simple

straight line regression analysis yielded correlation coefficients in the range of -0.93 to -0.99 for the variables ultimate tensile strength versus either accumulative pore area or percent pore area.

The overall results of this evaluation show the most valid predictor of weld ultimate tensile strength to be the pore area concept. Percent pore area is another way of expressing pore area per unit length of weld. Accumulative volume per unit length of weld is also shown to be a strong indicator of joint strength. The correlation coefficient value between accumulative linear units per unit length of weld and tensile strength was relatively poor when compared to the coefficients obtained by using either pore area or pore volume versus ultimate tensile strength.

INTRODUCTION

The acceptance of weldments in aluminum alloys is governed by both surface quality and internal quality. Undercutting, cracks, suck-back, burn-through, drop-through, lack of penetration, and misalignment are well known examples of objectionable surface defects. However, these problems can be recognized by visual or dye penetrant inspection. Undesirable internal defects are characterized by slag and dross inclusions, tungsten inclusions, lack of fusion, fissures, cracks, and porosity. Porosity is the major item observed in x-rays of welds. This investigation is concerned exclusively with spherical type macroporosity in an otherwise perfect weld in order that the effect of porosity alone upon joint weldment tensile properties can be examined. Porosity is generally caused by gaseous hydrogen bubbles [1]. The source of hydrogen is moisture and hydrocarbons which break down in the high temperature arc during welding [2].

Weldments generally show varying amounts of internal porosity, as detected by radiographic techniques. Weldments are sometimes rejected because porosity is considered as excessive in accordance to radiographic acceptance standards. In the past, the standards have been based for the most part on conservative engineering judgements. The general trend has been to establish arbitrary radiographic acceptance standards with porosity slightly larger in diameter and slightly greater in quantity than normally encountered in controlled production welds; thus, variations do exist in porosity acceptance standards from one specification document to another. To maintain production schedules, sometimes larger pores than permitted by a standard have been tolerated and waived. It is the consensus that in some cases a repair may result in a weld of lower quality than the original porosity-laden weld, though the

appearance of the repaired weld might be superficially better on the radiographic film [3]. However, leaving an intact large pore or accepting an array of pores not conforming to a specified acceptance standard leaves some doubt as to the structural integrity of the joint. Perhaps, existing standards are excessively stringent, and if so, how much relaxation is possible? The primary objective of this investigation is to determine to what degree tensile properties relate to porosity content, as expressed in terms of accumulative linear, volume, and area measurements of porosity per unit length of weld.

Welding engineers and metallurgists have attempted to introduce porosity in welds by faulty welding procedures, such as contaminating either the abutting edges, the shielding gases, or a combination of both. However, correlating the level of porosity to ultimate tensile strength by these techniques remains rather questionable. First, the purity as well as the physical metallurgical characteristics of the weld metal is altered. Second, reproduction of pore geometries and pore sizes into additional weld panels falls short of expectations. Third and probably most important, the fracture path should pass through the porosity, and not through other extraneous defects, such as dross and oxides which are associated normally with impure weld metal [4].

This investigation used weldments of the highest quality, with precision drilled holes simulating porosity along the surface of the weld interface (line of fusion) of each tensile specimen. Pore diameters, depths, and geometries were carefully controlled and measured exactly. Defects on or near the weld surface are considered more harmful than defects within (internal) the weld deposit [5, 6]. The fracture path of 2219-T87 weldments passes through the fusion zone on a single line which best fits the weld fusion lines. The normal fracture path of 2014-T6 weldments passes through only one side of the weld, and this being at the line of fusion or approximately normal to the base metal surface. Therefore, the specimens utilized in this investigation represented the worst conditions possible because (1) simulated porosity appeared at the surface, and (2) the simulated porosity was positioned along the normal fracture path. Specimen data are tabulated in the Appendix.

EQUIPMENT AND TEST SPECIMEN PREPARATION

The base materials (sheet and plate), the filler wires, and the shielding gases were all procured to appropriate aerospace specifications. The chemical composition limits of each base metal and filler wire are shown in Table 1.

Preweld sections (4 in. \times 24 in. = 10.6 cm \times 60.96 cm) used in this evaluation were fabricated from three thicknesses of 0.107-in. (0.272-cm) sheet, 0.250-in. (0.635-cm) plate, and 0.500-in. (1.27-cm) plate of 2014-T6, and also three thicknesses, 0.125 in. (0.318 cm), 0.250 in. (0.635 cm), and 0.500 in. (1.27 cm) of 2219-T87. The short direction (4 in. = 10.16 cm) of each panel was cut parallel to the principal rolling direction. All the panels were cleaned as follows:

1. Soaked with alcohol and rinsed in water.
2. Soaked in hot (approximately 200° F/93° C) non-etchant type alkaline cleaner for 10 to 15 minutes and rinsed in water.
3. Immersed 1 to 3 minutes in a solution of 0.5 percent hydrofluoric acid and 5.0 percent nitric acid, by volume.
4. De-smutted by immersing in a 50 percent, by volume, solution of nitric acid for 1 to 2 minutes, rinsed in water, and dried by wiping.

Final joint preparation consisted of draw filing the abutting edges, and scraping the two adjoining faces for a distance of approximately 3/4 in. (1.905 cm) away from the filed edge. These operations removed foreign matter embedded in the material surface, removed surface oxides, and removed gases absorbed in the material surface along the area to be welded. Figure 1 shows the metal surface removal locations and the configuration of a section.

The weldments were made by the TIG process on standard welding equipment, which consisted of an Airco Function Controlled welding power supply, Model FCWS-3049 and Model HMW-E voltage controlled welding head. Work pieces were held consistently by clamping fixtures, and travel speeds were provided by an automatic rack drive system. Square butt-joint weldments were made in the down hand (flat) position as shown by the welding setup in Figure 2. One weld pass was used to complete weldments in thicknesses up to 0.250 in. (0.635 cm). Two passes (one from each side) were required to weld 1/2-in. (1.27-cm) thick plate. Filler alloys were types 4043 and 2319 in combination with base alloys 2014 and 2219, respectively. Radiographic inspection followed procedures which usually grade weldments to Class I, per MSFC-SPEC-259A [7].

The weld bead reinforcements were machined flush and smooth (16 RMS) with the base metal surface. Tensile specimen configuration consisted of simple strips with parallel edges (Fig. 3) for ambient temperature testing, and a "dog bone" pin hole type specimen (Fig. 4) for testing at -320° F (-196° C).

Figure 1. Panel geometry.

A precision drilling machine was used to drill simulated porosity in test specimens. The machine was equipped with a X-Y coordinate table for precise positioning of the specimen and exact spacing of holes, a vise for holding and leveling the specimen, and a dial indicator for controlling the depth of each hole. Standard high speed precision twist drills were used to make all holes.

Drilling, spacing, and measuring procedures were as follows:

1. Hole diameters and depths were varied in twenty steps from 0.009 in. (0.023 cm) to 0.203 in. (0.516 cm); however, in no case did the hole diameter or depth exceed three-quarters of the base metal thickness.
2. The depth of each hole was controlled to equal the diameter of the drill. This was done to approach, as near as possible, simulated spherical-type porosity.
3. Single hole specimens consisted of one hole drilled at the weld fusion line, but mostly within resolidified metal, at a position which bisected the width of the tensile specimen.
4. Multiple hole specimens consisted of identical holes drilled in a straight line at two diameter intervals, along the weld fusion line as stated in paragraph 3. Each array of holes, from two up to fifty individual pores, was centered with regard to specimen width. A graphic representation is shown in Figure 5.

Figure 2. Flat weld position setup.

ORIGINAL PAGE IS
OF POOR QUALITY

Figure 3. Transverse weld tensile specimen configuration for testing at ambient temperature.

5. The maximum number of holes drilled in any given specimen was dictated by hole diameter, base metal thickness, and the spacing procedure as stated in procedure 4.

6. Drills were changed at selected intervals during the drilling operation. This was done to maintain a sharp and clean drill, which assured a consistent hole diameter throughout the drilling operation.

7. A typical hole for each drill diameter was made in 1/4-in. (0.635-cm) wide by 1/4-in. (0.635-cm) thick plate weldment at selected intervals during the drilling operation. Each specimen was radiographed, and the resultant film was used to exactly measure hole dimensions with the aid of a Mikon Tool Microscope. These dimensions were converted into pore area, pore volume, or linear inch (cm) of porosity. Reproductions of typical radiographs are shown in Figure 6. The dimensions, as measured from the radiographs, are shown in Table 2.

DISCUSSION AND RESULTS

In this evaluation, a technique was employed which introduced porosity (simulated) and still maintained normal metal quality along the deposited weld seam, or stated more specifically, the weld metal was not altered with regard to either purity or normal physical metallurgical characteristics. Weldments

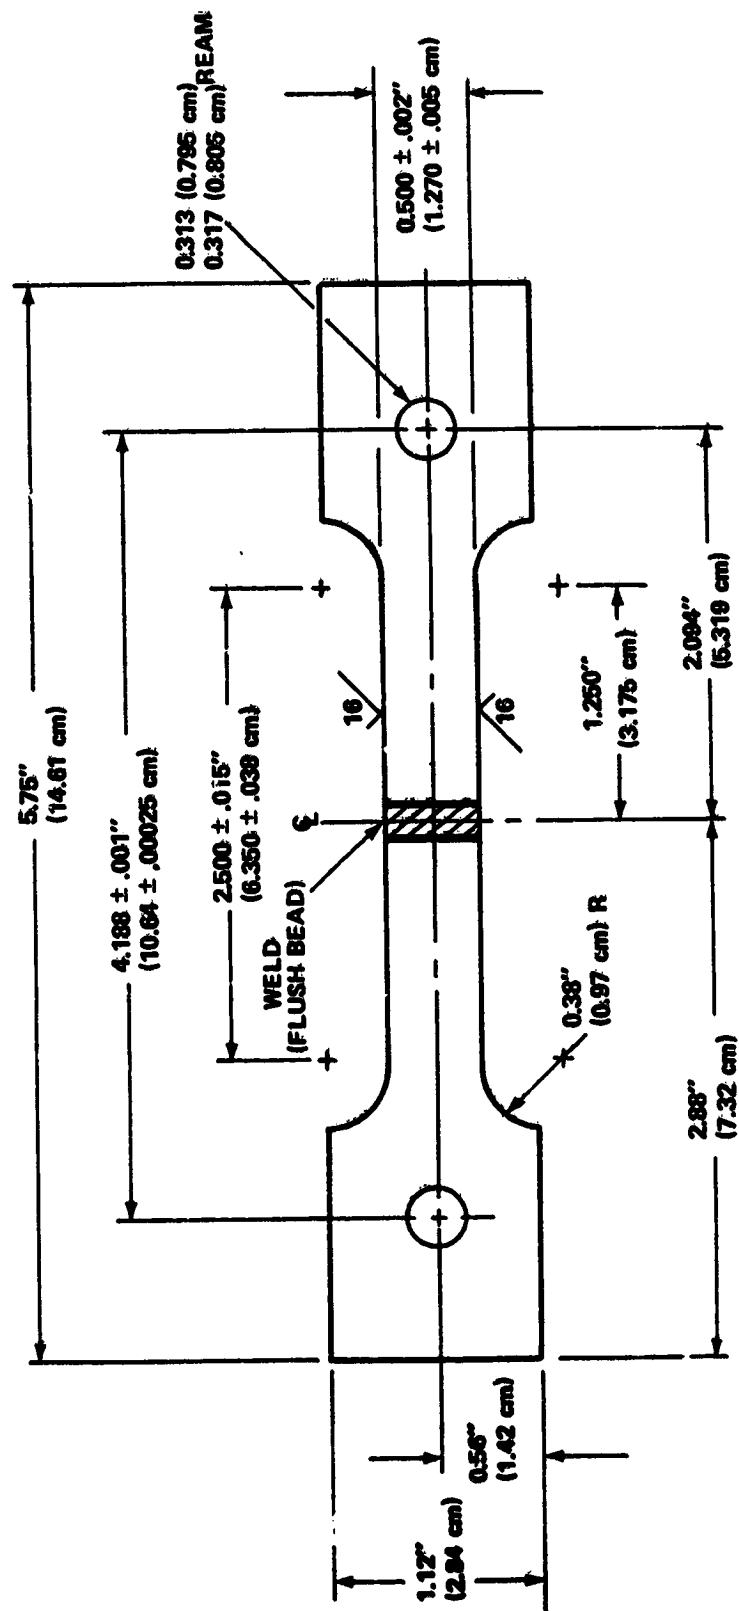

Figure 4. Transverse weld tensile specimen configuration for testing at -320° (-196° C).

were carefully selected with regard to initial quality and only weldments void of internal discontinuities, as disclosed by radiographic techniques, were used in this evaluation. The location of the simulated porosity was carefully positioned along the weld interface (line of fusion) which is included within the expected fracture plane.

NOTE: Each value shown is the average of three or more measurements.

The higher porosity (simulated) concentrations and larger diameters used in this effort greatly exceed those limitations imposed by existing aerospace specifications. Simulated porosity diameters ranged from 0.009 in. (0.023 cm) to 0.203 in. (0.516 cm). The accumulative porosity area, volume, and linear summation of pore diameters varied from 0 to 0.0717 in² (0.463 cm²), 0 to 0.0078 in.³ (0.0503 cm³), and 0 to 0.582 linear inch (1.478 cm), respectively, per linear inch (2.54 cm) of weld. The percent of pore area present in a unit length of weld varied from 0 to 36 percent. Pore diameter was measured by adding the long and short diameters and dividing by two. However, the two diameters (long and short) were approximately equal in most cases, and in only two cases did the two lengths vary by more than 0.006 in. (0.015 cm). The percent pore area was calculated by dividing the accumulative pore area by the cross-sectional area of the test specimen and multiplying by 100.

To determine quantitatively how much the pore concentration variable affects the mechanical properties of a weldment, a linear regression analysis statistical technique was applied. A simple, straight-line regression analysis was made when a linear trend was apparent after plotting accumulated data in scatter diagram. The ultimate tensile strength plots of the welds displayed the most significant correlation with simulated porosity level. Changes in yield strength and elongation values were either trivial or inconsequential in the lower and intermediate levels of porosity. In highly concentrated porosity-laden specimens, both yield strength and elongation values decreased markedly, as shown by the data obtained. The data used for this analysis are shown in the Appendix.

Simple, straight-line regression analysis fits a straight line to a series of points, as plotted by two variables. The correlation coefficient (r) is a measure of the linear relationship between two variables, and must be between +1.00 and -1.00. A correlation coefficient of +1.00 indicates a perfect direct linear relationship, while -1.00 would indicate a perfect inverse linear relationship. A correlation coefficient of zero indicates a complete absence of linear relationship. The square of the correlation coefficient (r^2) gives the percentage of total variation explained (fitted) or removed by the regression line [8].

If the linear relationship between two variables is assumed, the equation of the correlation coefficient is:

$$r = \frac{N(\sum XY) - (\sum X)(\sum Y)}{\sqrt{[N(\sum X^2) - (\sum X)^2][N(\sum Y^2) - (\sum Y)^2]}}$$

The equation of the least square line, or straight regression line of Y on X is:

$$Y' = a + bX$$

The slope b of the regression line is:

$$b = \frac{N(\sum XY) - (\sum X)(\sum Y)}{N(\sum X^2) - (\sum X)^2}$$

The Y-intercept (a) of the regression line [9] is:

$$a = \frac{\sum Y - b(\sum X)}{N}$$

Sample calculations of accumulative pore area versus ultimate tensile strength for each of three base weldment thicknesses are shown in Tables 3 and 4.

The porosity level was plotted against the corresponding tensile properties for each alloy, which included each thickness as a separate plot. Porosity level was expressed in terms of accumulative pore area, accumulative pore volume, and the accumulative linear pore diameter per unit length of weld, respectively, as well as percent pore area. Simple straight line regression analysis was performed because of the strong evidence of linear trends between ultimate tensile strength and the corresponding porosity level. The plots of the ultimate tensile strength versus percentage pore area for each thickness are presented in Figures 7 through 16.

All of the data plotted originated from measurements of 1,890 individual specimens tested at Marshall Space Flight Center (MSFC). The 2014-T6 specimens, welded with 4043, ranged in thickness from 0.107 in. (0.272 cm) to 0.500 in. (1.27 cm) and in width from 0.25 in. (0.635 cm) to 1.00 in. (2.54 cm). The number of individual pores drilled per specimen ranged from 0 to 50. The 2219-T87 specimens, welded with 2319, ranged in thickness from 0.125 in. (0.318 cm) to 0.500 in. (1.27 cm) and in width from 0.250 in. (0.635 cm) to 1.00 in. (2.54 cm). The number of individual pores drilled per specimen ranged from 0 to 40. Tests were made at room temperature in air and at -320°F (-196°C) in liquid nitrogen.

In general, accumulative pore area and percent pore area in weldments of each alloy displayed a very strong linear relationship with ultimate tensile strength. Simple straight line regression analysis yielded correlation coefficients (r) which exceeded -0.900 , and the square of the coefficients (r^2) was in excess of the numerical value of 0.81 . In essence, this means that more than 81 percent of the total ultimate tensile strength variation can be explained by the associated accumulative pore area or percent pore area. In some cases, the correlation coefficients actually surpassed the numerical value of -0.980 . These two quantities are grouped together because percent pore area is only a slight mathematical refinement of accumulative pore area. Percent pore area by this method of calculation takes into account the small change in cross-sectional area from specimen-to-specimen. The maximum allowable percentage of porosity for the worst single linear inch of weld permitted by MSFC specifications 259A and 504 [7, 10] are shown for each thickness in the plots of Figures 7, 8, 9, 11, 12, and 13. These allowables represent the worst single inch in six continuous linear inches of weld in the case of 259A, and the worst one inch in three continuous linear inches of weld in the case of 504.

Accumulative pore volume per unit length of weld is also shown to be an excellent indicator of tensile strength. Overall, these correlation coefficient values were slightly lower than those values which were obtained by using the pore area concept.

The linear relationship between ultimate tensile strength and accumulative linear inch of porosity per unit length of weld was the weakest, as indicated by the resultant correlation coefficients. The coefficients varied from -0.591 to -0.872 , with a majority of the values in the -0.750 range. Therefore, the accumulative linear inch concept is not considered as a good indicator to describe the effect of porosity upon weld joint strength degradation.

The ultimate tensile strength for each individual value (all thicknesses combined) was plotted as a function of corresponding percent pore area for each alloy (Figs. 10 and 14). These combined data exhibited a correlation coefficient of -0.882 for weldments of aluminum alloy 2014-T6, and a coefficient of -0.913 for weldments of alloy 2219-T87.

Tensile tests conducted at -320°F (-196°C) with $1/4$ -in. (0.635 -cm) plate weldments also showed a strong linear relationship between ultimate tensile strength and accumulative simulated pore area or percent pore area (Figs. 15 and 16). Simple straight line regression analysis resulted in a correlation coefficient of approximately -0.94 for both alloys. Tensile strength as a function of accumulative pore volume showed a correlation coefficient greater than

-0.88 for both alloys; whereas, using the accumulative linear inch concept, the coefficients were -0.799 and -0.708 for alloy 2014-T6 and alloy 2219-T87, respectively. The resultant correlation coefficients are shown in Tables 5 and 6.

Remarkably, the linear relationship between ultimate tensile strength and accumulated pore area held from 0 to 30 percent pore area at room temperature and from 0 to 15 percent pore area at -320°F (-196°C). These were the highest values of pore area tested and did not necessarily represent a limiting pore area. Another fact which is obvious from reviewing Figures 7 through 16 is that the ultimate strength is reduced linearly to 63 percent of its initial value at 30 percent pore area (70 percent gross cross section of weld metal remaining). This indicates the toughness of these welds in the presence of spherical porosity.

CONCLUSIONS

Tensile properties in defect-free, weldments of aluminum alloy 2014-T6 or 2219-T87 (sheet and plate) are shown to be related to the level of induced simulated porosity. The scatter diagram (strength-porosity graph) showed that the ultimate tensile strength of the weldments displayed the most pronounced linear relationship with the level of porosity. (Yield strength and elongation decreased rapidly at high pore concentrations).

Accumulative pore area or percent pore area displayed the best linear relationship with ultimate tensile strength. Accumulative pore volume also displayed a strong relationship with ultimate tensile strength; whereas, accumulative linear pore diameters indicated a relatively weak relationship with weld strength.

Simple straight line regression analysis of tensile data (considering all thicknesses) showed that (a) 81 to 97 percent of the total ultimate tensile strength variation can be explained by the associated accumulative pore area concept, (b) 76 to 91 percent of the total ultimate tensile strength variation can be attributed to the associated accumulative pore volume, and (c) only 34 to 76 percent of the total ultimate tensile strength variation can be attributed to the associated linear accumulation of pore diameters. Tensile tests conducted at -320°F (-196°C) displayed similar linear trends between corresponding variables.

In summation, the selected relationship between weldment ultimate tensile strength and accumulative pore area may be treated as linear, provided only those pores which pass through the fracture path are considered for correlation purposes. However, the linear relationship holds to much greater pore concentrations than are currently allowed. Other internal defects, such as fissure, dross, sharp tails, lack of fusion, and impure weld metal, will undoubtedly affect the strength of the weld but were avoided to obtain the correlation of spherical-type porosity. Nevertheless, this relationship based on accumulative pore area, as detected by radiographic techniques, in combination with known design load requirements will serve as an engineering guideline in determining when a weld repair is necessary or when porosity is acceptable. In addition, this same relationship makes possible an assessment of existing radiographic acceptance standards, and it has been applied to determine the porosity levels in MSFC-SPEC-504.
